ABSTRACT

We compute the non-thermal emissions produced by relativistic particles accelerated by the AGN-driven shocks in NGC 1068, and we compare the model predictions with the observed γ -ray and radio spectra. The former is contributed by pion decay, inverse Compton scattering, and bremsstrahlung, while the latter is produced by synchrotron radiation. We derive the γ -ray and radio emissions by assuming the standard acceleration theory, and we discuss how our results compare with those corresponding to other commonly assumed sources of γ -ray and radio emissions, like Supernova remnants (SNR) or AGN jets. We find that the AGN-driven shocks observed in the circumnuclear molecular disk of such a galaxy provide a contribution to the γ -ray emission comparable to that provided by the starburst activity when standard particle acceleration efficiencies are assumed, while they can yield the whole γ -ray emission only when the parameters describing the acceleration efficiency and the proton coupling with the molecular gas are tuned to values larger than those assumed in standard, SNR-driven shocks. We discuss the range of acceleration efficiencies (for protons and electrons) and of proton calorimetric fractions required to account for the observed γ -ray emission in the AGN outflow model.

We further compare the neutrino flux expected in our model with constraints from current experiments, and we provide predictions for the detections by the upcoming KM3NeT neutrino telescope. This analysis strongly motivates observations of NGC 1068 at \gtrsim TeV energies with current and future Cherenkov telescopes in order to gain insight into the nature of the γ -rays source.

Key words. galaxies: individual: NGC 1068, galaxies: Seyfert, gamma rays: galaxies, radiation mechanisms: non-thermal

1. Introduction

NGC 1068 is the brightest, closest and best studied Seyfert 2 galaxy. The discovery of its Seyfert 1 nucleus in polarized light led Antonucci & Miller (1985) to propose the AGN unification model. In its central region this source exhibits both starburst and AGN activities. Interferometric observations in the millimetre (mm) band identified a circumnuclear disk (CND) ~ 200 pc in radius, surrounded by a ~ 2 kpc starburst ring connected to the CND by a bar. In X-rays, the spectrum is dominated by reflection components of the primary AGN radiation by Compton thick material (i.e. with column density $N_H > 1.5 \times 10^{24} \text{ cm}^{-2}$), and in particular by a strong $K\alpha$ iron line ($EW \approx 1$, Matt et al. 2004). Recently Marinucci et al. (2016) detected a transient flux excess at energies above 20 keV that can be explained by a temporary decrease of N_H along the line of sight. This event allows to unveil the primary AGN emission and to infer an intrinsic 2–10 keV luminosity of $L_X = 7 \times 10^{43} \text{ erg/s}$ (corresponding to bolometric luminosity $L_{AGN} \approx 2.1 \times 10^{45} \text{ erg/s}$, Marconi et al. 2004).

NGC 1068 is a strong γ -ray emitter. It is the brightest of the few non-blazar galaxies detected by the *Fermi Gamma-ray space telescope* and with the flattest γ -ray spectrum (Ackermann et al.

2012). Models assuming that the γ -ray emission is entirely due to starburst activity failed to reproduce the observed spectrum (Yost-Hull et al. 2014; Eichmann & Becker Tjus 2016). This suggests an alternative/complementary origin for the γ -ray emission (see e.g. Lenain et al. 2010).

Interestingly, sub-mm interferometry of molecular lines in the CND strongly suggests the existence of a giant, AGN-driven outflow which extends to ~ 100 pc scale with velocity of $\sim (100\text{--}200)$ km/s (Krips et al. 2011; García-Burillo et al. 2014). This outflow can induce shocks in the CND, which, in turn, can accelerate relativistic particles with an efficiency that may exceed that in Supernova remnant (SNR) and could leave observational signatures in different electromagnetic bands (Faucher-Giguère & Quataert 2012; Nims et al. 2015). In addition to primary accelerated electrons, the decay of neutral pions created by collisions between relativistic protons accelerated by the AGN shocks with ambient protons may produce a significant γ -ray emission. This hadronic γ -ray emission is mostly favored as the dominant component of the γ -ray spectrum at energies above ≈ 100 MeV. At lower energies leptonic processes like inverse Compton (IC) scattering and non-thermal bremsstrahlung can significantly contribute to the γ -ray emission. The same electrons responsible for IC and bremsstrahlung emission spiraling in interstellar magnetic fields radiate synchrotron emission in the radio continuum. The interpretation of the radio emission as a

by-product of the AGN-driven outflow activity could in part explain the deviation of NGC 1068 from the observed correlation between the radio and far infrared (FIR) luminosities of star forming galaxies. The FIR-radio correlation spans over five orders of magnitude in luminosity, from dwarf galaxies to starburst galaxies (Condon et al. 1991; Yun et al. 2001) and has been explained in terms of FIR emission related to dust heated by young massive stars, and radio emission associated to relativistic electrons accelerated in SNR. NGC1068 is observed to have about four times larger radio luminosity than expected from the radio-FIR correlation (Yun et al. 2001).

Radio emission from AGN-driven outflows can also explain the strong correlation between the kinematics of the ionized gas emission and the radio luminosity observed in obscured radio-quiet quasars at $z \lesssim 1$ (Zakamska & Greene 2014).

In this picture, the γ -ray and radio luminosities are determined by the energy supplied to relativistic protons and electrons at the shock. In this paper we examine if the kinetic power of the AGN-driven outflow observed in NGC 1068 can account for the observed γ -ray and radio luminosities.

The paper is organized as follows. An overview of the observational data, including our *Fermi* Large Area Telescope (LAT) data analysis, is given in Section 2. The physical processes involved in the cosmic-ray (CR) particle energy distributions and the non-thermal emission produced by accelerated particles are described in Section 3. In Section 4 we present our results, discussion and conclusion follow in Section 5 and 6.

Throughout the paper, we use a vacuum-dominated cosmological model with $\Omega_m=0.3$, $\Omega_\Lambda=0.7$, and $H_0=70 \text{ km s}^{-1} \text{ Mpc}^{-1}$; and we adopt a distance to NGC 1068 of 14.4 Mpc, so that $1'' \simeq 70 \text{ pc}$.

2. Observational data

In this Section we review the general structure and physical properties of the central region of NGC 1068, which we will use in the computation of the non-thermal emissions from accelerated particles in the AGN-driven shocks.

NGC 1068 has been the target of several observational campaigns over the entire electromagnetic spectrum.

In the radio band the continuum emission is spatially resolved into different structures: a 3 kpc diameter star-forming disk, a kpc-scale radio jet, and a 100 pc-scale jet and compact radio knots (e.g. Gallimore et al. 1996; Wynn-Williams et al. 1985; Gallimore et al. 2006; Sajina et al. 2011; Hönig et al. 2008).

Near-IR observations of the narrow line region (NLR) revealed that the NLR gas is outflowing in a bicone that follow the path of the radio jet (Müller-Sánchez et al. 2011; Barbosa et al. 2014).

The distribution and kinematics of the molecular gas in the galaxy disk have been mapped through molecular line surveys (Müller Sánchez et al. 2009; Krips et al. 2011; García-Burillo et al. 2014; Barbosa et al. 2014; García-Burillo et al. 2016; Gallimore et al. 2016). High resolution Atacama Large Millimetre/submillimetre Array (ALMA) observations spatially resolved the kinematics of the molecular gas within the few parsecs from the nucleus (the putative obscuring torus). The kinematics of the molecular gas in the torus show strong non-circular motions consistent with a bipolar outflow along the axis of the AGN accretion disk, similar to the outflow inferred for the NLR gas (García-Burillo et al. 2016; Gallimore et al. 2016). At larger scales ALMA observations revealed a starburst ring of radius $\sim 2 \text{ kpc}$ and a CND. In CO maps the CND appears

as an asymmetric ring of $350 \text{ pc} \times 200 \text{ pc}$ size. The ring shows a rich substructure with two prominent knots located east and west of the position of the AGN.

By combining ALMA and *Herschel* observations García-Burillo et al. (2014) derived the molecular gas mass of the CND from SED fitting of the dust continuum emission. They estimated $M_{\text{gas}} \simeq (5 \pm 3) \times 10^7 M_\odot$, which corresponds to a gas surface density $\Sigma_{\text{gas}} \simeq (0.01-0.05) \text{ g cm}^{-2}$ and to a gas number density $n_H \simeq (115-460) \text{ cm}^{-3}$ assuming a cylindrical geometry with radius $R = 350 \text{ pc}$ and vertical scale height $h \simeq 10 \text{ pc}$ (Schinnerer et al. 2000).

The above estimate of the gas surface density can be used to estimate the volume averaged interstellar medium (ISM) magnetic field strength of the CND $B_{\text{ISM}} \simeq (30-110) \mu\text{G}$ from their empirical scaling relation $B_{\text{ISM}} \simeq (30-110) \mu\text{G}$ (Robshaw et al. 2008; McBride et al. 2014).

2.1. Properties and powering source of the molecular outflow

A sizeable fraction of the total gas content in the CND is involved in a massive outflow (Krips et al. 2011; García-Burillo et al. 2014; Barbosa et al. 2014). The most relevant outflow properties in the derivation of the non-thermal emissions from shock accelerated particles is the kinetic energy injected into the ISM during the outflow time-scale (see Sect. 3.1). The kinetic luminosity of the outflow is given by its bulk motion, and can be derived from the expression:

$$L_{\text{kin}} = \frac{1}{2} \times \frac{dM_{\text{out}}}{dt} \times v_{\text{out}}^2 \quad (1)$$

where dM_{out}/dt is the mass outflow rate and v_{out} is the outflow velocity.

From the broad CO(3-2) components in their spectra García-Burillo et al. (2014) estimated the outflowing gas mass $M_{\text{out}} = 1.8 \times 10^7 M_\odot$, the average radial extent of the outflow $R_{\text{out}} = 100 \text{ pc}$, and the projected radial outflow velocity $v_{\text{out},p} \simeq 100 \text{ km/s}$. Assuming a multi-conical outflow geometry they derived the mass outflow rate as $dM_{\text{out}}/dt = 3 \times v_{\text{out},p} \times M_{\text{out}}/R_{\text{out}} \times \tan \alpha \simeq 63 M_\odot \text{ yr}^{-1}$; here α is the unknown angle between the outflow and the line of sight. They assumed that the outflow is coplanar with the main disk, i.e. $\tan \alpha = 1/\tan i$ where $i = 41^\circ$ is the disk inclination angle, and, by replacing v_{out} with $v_{\text{out},p}/\cos \alpha$ in eq. (1), they estimated an outflow kinetic luminosity equal to $L_{\text{kin}} \simeq 5 \times 10^{41} \text{ erg/s}$. The main uncertainty of this estimate is due to the unknown inclination angle between the outflow and the line of sight.

Here we estimate L_{kin} without any assumptions about the inclination angle α . To this purpose, assuming that the outflow is isotropic we infer a maximum outflow velocity¹ $v_{\text{max}} \simeq 200 \text{ km/s}$ directly from the CO(3-2) spectra obtained with the Submillimeter Array (SMA) by Krips et al. (2011). We estimate the mass outflow rate as $dM_{\text{out}}/dt = 3 \times v_{\text{max}} \times M_{\text{out}}/R_{\text{out}} \simeq 108 M_\odot \text{ yr}^{-1}$, and the kinetic luminosity from eq. (1) with $v_{\text{out}} = v_{\text{max}}$. We derive $L_{\text{kin}} = 1.5 \times 10^{42} \text{ erg/s}$.

The kinetic luminosity of the outflow indicates that AGN activity rather than star formation is the likely powering source of the outflow. Indeed, the star formation rate for the circumnuclear region out to a radius $R \simeq 140 \text{ pc}$ is $\text{SFR} \simeq 1 M_\odot/\text{yr}$ (Esquej et al. 2014). This corresponds to a supernovae rate

¹ We compute the maximum velocity as in Rupke & Veilleux 2011

$v_{SN} \approx 0.01 \text{ yr}^{-1}$ for a Kroupa initial mass function (Kroupa 2001). Assuming a typical kinetic energy from a supernovae explosion of $E_{SN} = 10^{51} \text{ erg}$, the kinetic luminosity associated to star formation is $L_{kin} = v_{SN} E_{SN} \approx 3 \times 10^{41} \text{ erg/s}$.

The jet power derived from the luminosity at 1.4 GHz $L_{jet} = 1.8 \times 10^{43} \text{ erg/s}$ (García-Burillo et al. 2014), and the bolometric luminosity of the active nucleus estimated from mid-IR and X-ray bands $L_{AGN} = (4.2 \times 10^{44} - 2.1 \times 10^{45}) \text{ erg s}^{-1}$ (Bock et al. 2000; Alonso-Herrero et al. 2011; García-Burillo et al. 2014; Marinucci et al. 2016) indicate that the interaction of the CND gas with either the AGN jet and/or the energy released during accretion of matter onto supermassive black hole are able to drive the molecular outflow.

2.2. γ -ray spectrum

In the very high energy part of the electromagnetic spectrum NGC 1068 was observed by *Fermi*. Here we present our analysis of NGC 1068 *Fermi*-LAT data. The LAT instrument (Atwood et al. 2009) detects γ -rays in the energy range extending from 20 MeV to more than 300 GeV, by measuring their arrival time, energy and direction. We analyzed NGC 1068 *Fermi*-LAT data collected from August 8th, 2008 to February 28th, 2016 in the energy range 100 MeV–300 GeV. We used the FERMI SCIENCE TOOLS (version v10r0p5) to produce and analyse cleaned and filtered event files, following the data analysis thread provided by the *Fermi* Science Support Center². We considered the Pass 8 data (evclass=128 & evtype=3) and only events with zenith angles $< 90^\circ$ to minimize the contamination from the Earth Limb. We filtered the data using good time intervals generated using the task GTMKTIME, with expression recommended by the LAT team of (DATA QUAL>0)&&(LAT CONFIG==1). We adopted the “P8R2 SOURCE V6” instrumental response function (IRF).

The events are selected from a $40^\circ \times 40^\circ$ squared region of interest (ROI), centered on NGC 1068. We used the binned maximum likelihood method to obtain the NGC 1068 spectral energy distribution. Our model includes all known sources in the *Fermi*-LAT 4-Year Point Source catalogue (3FGL, Acero et al. 2015), the diffuse Galactic background (gll_iem_v06.fits) and diffuse extragalactic component (iso_P8R2_SOURCE_V6_v06.txt). The model file was generated with make3FGLxml.py6. We left free to vary only the brightest and variable sources in the ROI; moreover, the make3FGLxml.py script automatically adds 10° to the ROI, to account for sources that lie outside, but which may provide a photon contribution to our data. We also included a new source, not included in the 3FGL, located at a distance less than 4° from NGC 1068, centered on the peak of the LAT 100 MeV–100 GeV emission, modelled with a power-law model with free normalization and photon spectral index. This source is a factor of ~ 3 brighter than NGC 1068 in the 100–300 MeV energy range, with $\sqrt{TS} \sim 11^3$ and could be the counterpart of the 5BZQJ0239+0416 QSO R1oud flat-spectrum radio quasars (Massaro et al. 2015), located at a distance $\sim 15'$ from its LAT position. We found that NGC 1068 is fainter at energies 100–300 MeV than in the 3FGL catalogue. We verified that this is due to the addition of the new source. In fact, owing to the large low energy PSF (i.e. 95% PSF is $\sim 10^\circ$ at $\sim 100 \text{ MeV}$), the 3FGL

flux is probably overestimated, including part of the emission of the new source.

At energies $> 10 \text{ GeV}$ we found a spectral shape different from that of the 3FGL. This discrepancy is ascribed to the splitting of the energy bin, indeed using the same single bin (10–100 GeV) we reproduce the 3FGL results. Our analysis indicates a significant ($\sim 5 \sigma$) γ -ray emission at energies 10–30 GeV, while in the 30–100 GeV energy range we obtain only an upper limit. The 3σ upper limit is computed as follows: if T is the total number of counts measured at the position of a source, B are the expected background counts, and X are the unknown counts from the source, the 3σ (99.7%) upper limit on X can be defined as the number of counts X that gives a 0.3% probability to observe T (or less) counts. Applying the Poisson probability distribution function, X is therefore obtained by iteratively solving for different X values in the following equation:

$$0.003 = e^{-(X+B)} \sum_{i=0}^T \frac{(X+B)^i}{i!} \quad (2)$$

(see e.g., Narsky 2000)

We collected the counts T from a region centered on NGC 1068 with 1° radius, which contains more than 95% PSF, and estimated the B expected background counts in source free neighboring regions. Finally we evaluated the flux from the counts applying the vignetting corrected exposure time stored in the exposure maps.

The spectrum obtained from this analysis as well as the 3FGL spectrum are shown in figure 2 (see also table 1).

3. Theoretical modelling

3.1. Accelerated particle spectra

To build-up a model that predicts the γ -ray and radio spectra, we must first calculate the CR spectra.

CR particles are subject to a number of energy loss processes which cause distortions of their injection spectra as they propagate through the ISM. In the case of relativistic protons, pions production through inelastic collisions with ambient protons is the dominant loss mechanism. The collisional energy loss time-scale is given by:

$$\tau_{pp} \approx 5 \times 10^7 \text{ yr} \left(\frac{n_H}{\text{cm}^{-3}} \right)^{-1} \quad (3)$$

where n_H is the ISM gas density.

Protons can also escape from the acceleration region. The time-scale on which CR particles are advected in the AGN-driven outflow is:

$$\tau_{out} = \frac{R_{out}}{v_{out}}. \quad (4)$$

From the above equations we compute the residence time of CR protons τ_p as:

$$\tau_p = (\tau_{pp}^{-1} + \tau_{out}^{-1})^{-1}. \quad (5)$$

A galaxy becomes a proton calorimeter when the residence time approximately equals the collisional energy loss time-scale ($F_{cal} \equiv \tau_p / \tau_{pp} = 1$).

² <http://fermi.gsfc.nasa.gov/ssc/data/analysis/scitools/>

³ The TS value is defined as $TS = -2(L0 - L1)$, where L0 and L1 are the logarithmic maximum likelihood values of null hypothesis and tested model including the target source. The square root of the TS is approximately equal to the detection significance for a given source.

For relativistic electrons, the loss mechanisms involve interactions with matter, magnetic field, and radiation. For a gas density n_H the energy loss rate due to bremsstrahlung emission is:

$$-\left(\frac{dE}{dt}\right)_{brem} = 3.66 \times 10^{-7} \left(\frac{E}{eV}\right) \left(\frac{n_H}{cm^{-3}}\right) eVs^{-1} \quad (6)$$

while the loss rate due to ionization is:

$$-\left(\frac{dE}{dt}\right)_{ion} = 7.64 \times 10^{-15} n_H (3 \ln(E/m_e c^2) + 19.8) eVs^{-1}. \quad (7)$$

The synchrotron cooling rate is given by:

$$-\left(\frac{dE}{dt}\right)_{syn} = \frac{4\sigma_T c E^2 U_B}{3(m_e c^2)^2} \quad (8)$$

where m_e is the electron mass, $\sigma_T = 6.65 \times 10^{-25} cm^2$ is the Thomson cross section, and $U_B = B_{ISM}^2 / 8\pi$ is the magnetic energy density. Finally, the energy loss rate of a relativistic electron by IC scattering in the Thomson approximation is:

$$-\left(\frac{dE}{dt}\right)_{IC} = \frac{4\sigma_T c E^2 U_{rad}}{3(m_e c^2)^2} \quad (9)$$

where $U_{rad} = L_{AGN} / 4\pi c R_{out}^2$ is the radiation energy density at the location of the shock (R_{out}), and L_{AGN} is the AGN luminosity⁴. The full Klein-Nishina cross section is used to compute the IC cooling time-scale and the photon emission (see fig. 1 and Section 3.3.2). Klein-Nishina effects imply a significant reduction of the CR electron energy loss rate compared to the Thomson limit (see e.g. Schlickeiser & Ruppel 2010).

The residence time of CR electrons with energy E is therefore:

$$\tau_e = \frac{E}{(dE/dt)} \quad (10)$$

where (dE/dt) is the sum of the processes described in eq. (6)-(9).

Figure 1 shows the residence times of CR protons and electrons in the CND of NGC 1068 as a function of the particle's energy. The time-scale on which CR particles are advected in the AGN-driven molecular outflow (τ_{out}) is also shown. The latter is comparable to the proton residence time, but much longer than the electron residence time. This implies that CR protons either interact with the CND gas or escape in the outflow, whereas CR electrons predominantly stay and cool in the CND.

The evolution of the CR energy spectrum as the particles diffuse from their source under conditions of energy losses is given by the diffusion-loss equation. If the time-scale for particle acceleration is smaller than all other time-scales (energy loss or escape) than the system will be in a steady state. The steady-state diffusion-loss equation for CRs with no spatial and temporal dependence is (Longair 2011):

$$\frac{N(E)}{\tau_{life}(E)} - \frac{d}{dE} [b(E)N(E)] - Q(E) = 0 \quad (11)$$

where E is the total energy, $N(E)$ is the CR spectrum, $Q(E)$ is CR source function, $b(E) = -(dE/dt)$ is the cooling rate of individual CR, and $\tau_{life}(E)$ is the lifetime to diffusive or advective

escape from the system.

Since pion production can be identified as a catastrophic loss (Torres 2004; Lacki & Beck 2013), the final proton spectrum can be obtained by solving eq. (11) with $b(E) \rightarrow 0$:

$$N_p(E) \simeq Q_p(E) \tau_p \quad (12)$$

where τ_p is the residence time of CR protons given in eq. (5). Note that the latter neglects diffusion losses. The role of diffusive escape constitutes a source of uncertainty in the computation. On the other hand, energy-dependent diffusion losses soften the γ -ray spectrum. The hard \gtrsim GeV spectrum found for NGC 1068 suggests that the energy losses due to either hadronic interactions or advection dominate over diffusion losses. In the following we will neglect diffusion losses for both CR protons and electrons.

Since escape (advective and diffusive) is negligible for CR electrons ($\tau_{life}(E) \rightarrow 0$) the final spectrum will have the form:

$$N_e(E) \propto \frac{Q_e(E) \tau_e(E)}{p-1} \quad (13)$$

if the spectrum of the injected electrons has the form $Q(E) \propto E^{-p}$.

It is generally believed that particle acceleration in strong shock waves, often referred as diffusive shock acceleration (DSA), is the primary mechanism producing energetic particles in astrophysical shocks (but see Vazza et al. 2015, 2016; van Weeren et al. 2016 for results showing that DSA has difficulties in explaining the observed emissions of particles accelerated in galaxy cluster shocks). DSA could result in the production of a power-law CR population with a power-law index $p \simeq 2$ (Bell 1978a,b; Blandford & Ostriker 1978; Drury 1983), that extends to energies as high as is permitted by various loss processes. Here we assume that DSA is effective in AGN-driven shocks, so we assume for the source functions the form:

$$Q_p(E) = A_p E^{-p} \exp \left[- \left(\frac{E}{E_{max,p}} \right) \right] \quad (14)$$

and

$$Q_e(E) = A_e E^{-p} \exp \left[- \left(\frac{E}{E_{max,e}} \right) \right] \quad (15)$$

where the normalization constants A_p and A_e are determined by the total energy supplied to relativistic protons and electrons at the shock respectively, and $E_{max,p}$ and $E_{max,e}$ are the maximum energies of accelerated protons and electrons.

As AGN-driven outflow is the assumed driver of CR acceleration, the CR particle spectrum must be related to the total energy input from the AGN:

$$\int_{E_{min}}^{E_{max}} N(E) E dE = \eta \int_{\tau_{out}-\tau}^{\tau_{out}} L_{kin}(t) dt \quad (16)$$

here L_{kin} is the kinetic luminosity of the outflow, η is the fraction of the kinetic energy transferred to CR particles, τ_{out} is the outflow time-scale, and τ is the residence time of CR particles. The physics governing the acceleration of particles in non-relativistic AGN-driven outflows is not well known, in particular we have no indication of the particle's acceleration efficiency. A general indication can be obtained by viewing AGN-driven outflows as a SNR analogue. The comparison between the γ -ray and radio emissions from SNR and the kinetic energy supplied by supernova explosions suggest $\eta_p \simeq (0.1-0.2)$ for CR protons and

⁴ The IR luminosity derived from the circumnuclear SFR and the SFR- L_{IR} relation (Kennicutt 1998; Rieke et al. 2009) is $L_{IR} \simeq 3.3 \times 10^{43} \text{ erg s}^{-1}$. Thus within the CND the energy density of the AGN radiation field overwhelms that of the stellar component.

$\eta_e \simeq (0.01-0.02)$ for CR electrons (Keshet et al. 2003; Thompson et al. 2006; Tatischeff 2008; Lacki et al. 2010, and references therein).

The maximum energy of accelerated particles depends on the age or size of the accelerator, on the particle energy-loss processes, and on the scale λ of the particle diffusion length. The expressions for the maximum achievable energy in the SNR context are given in Reynolds (2008):

$$E_{max,age} = 0.5v_{s,8}^2 t_{age,3} B_{\mu G} f^{-1} TeV \quad (17)$$

$$E_{max,loss} = 100v_{s,8}(fB_{\mu G})^{-0.5} TeV \quad (18)$$

$$E_{max,esc} = 10B_{\mu G} \lambda_{17} TeV \quad (19)$$

where $v_{s,8}$ is the shock velocity in units of 10^8 cm/s, $t_{age,3}$ is the age of the accelerator in units of 10^3 yr, $B_{\mu G}$ is the magnetic field strength in units of μG , λ_{17} is the diffusion length in units of 10^{17} cm, and f parametrizes diffusion effects ($f \simeq 1$ for Bohm diffusion).

3.2. The physics of AGN-driven galactic outflows

The normalizations of the CR proton and electron spectra (eq. 16) depend on the kinetic energy injected into the ISM by the AGN-driven outflow during the residence time of CR particles. In this context, the most important question regarding the physics of AGN-driven galactic outflows is whether or not the outflow kinetic luminosity is constant in time.

Theoretical models postulate that the galactic non-relativistic outflows are produced when wide-angle fast winds ($v \simeq 0.1-0.3 c$) shock against the galaxy ISM (e. g. King 2003; King & Pounds 2003; King et al. 2011; Lapi et al. 2005; Faucher-Giguère & Quataert 2012; Zubovas & King 2012; Zubovas & Nayakshin 2014). These mildly relativistic winds are observed in the central regions of AGN (e.g. Chartas et al. 2002; Pounds et al. 2003; Reeves et al. 2003; Tombesi et al. 2010, 2015), and likely originate from the acceleration of gas particles in the accretion disk around super massive black holes by the AGN radiation field.

The fast wind impact implies a reverse shock that slows the wind and injects energy into the ISM. The shocked wind acts like a piston sweeping up the ISM. The supersonic swept up gas drives a forward shock into the ISM, which is separated from the reverse shock by a contact discontinuity.

The cooling of the shocked fast wind determines whether the outflow kinetic energy is conserved (King et al. 2011; Faucher-Giguère & Quataert 2012). If the shocked wind gas cools efficiently, most of the pre-shock kinetic energy is lost (usually to radiation), and only its momentum flux is transferred to the ISM (momentum-driven outflow). On contrast, if the cooling of the shocked wind gas is inefficient, the shocked wind gas retains all the mechanical luminosity thermalized in the shock, and expands adiabatically pushing the ISM gas away (energy-driven outflow). In this case the momentum flux of the swept-up material in the ISM increases with time owing to the work done by the shocked gas. The expected momentum boost is predicted to be $(dP_{out}/dt)/(L_{AGN}/c) \simeq 10-100$ (Zubovas & King 2012; Faucher-Giguère & Quataert 2012), where $(dP_{out}/dt) = (dM_{out}/dt)v_{out}$ is the momentum flux of the large-scale outflow, and L_{AGN}/c is the momentum flux of the fast wind accelerated by AGN radiation pressure.

By comparing the IC cooling time-scale of the shocked wind and

the outflow time-scale King (2003) (see King & Pounds 2015 for a review) found that momentum-driven outflows are confined to the nuclear region of galaxies, while energy-driven outflows affect larger scale (but see Faucher-Giguère & Quataert 2012 for different results implying energy-driven outflow for a wide range of parameters characteristic of real galaxies).

Overall, the observations of kpc-scale AGN-driven molecular outflows in ultra luminous infra-red galaxies (ULIRGs) indicate large values of the ratio $(dP_{out}/dt)/(L_{AGN}/c)$ strongly suggesting the energy-driven regime for these outflows (e.g. Fischer et al. 2010; Sturm et al. 2011; Rupke & Veilleux 2011; Feruglio et al. 2010, 2015; Ciccone et al. 2014). However, for the more compact molecular outflow observed in NGC 1068 we are not in the position to clearly distinguish its nature. Indeed, assuming the outflow mass rate and velocity derived in Section 2 we find $(dP_{out}/dt) = 1.4 \times 10^{35} \text{ g cm s}^{-2}$. The latter is a moderate factor $\sim (2-10)$ larger than $(L_{AGN}/c) = (1.4 \times 10^{34} - 0.7 \times 10^{35}) \text{ g cm s}^{-2}$. Thus in the next sections, we will derive the γ -ray and radio emission by assuming both an energy-driven and a momentum-driven outflow. In the former case, L_{kin} is assumed constant in eq. (16), and equal to the kinetic luminosity derived from sub-mm interferometry (see Section 2). In the latter case, L_{kin} varies in time. Since the kinetic luminosity $L_{kin} \propto (dM_{out}/dt)v_{out}^2 \propto \rho(R)R^2v_{out}^3$, in order to estimate the total kinetic energy injected into the ISM during the residence time of CR particles from the measured kinetic power we need to know the gas density profile and the dynamics of the expansion.

To this purpose we adopt the models of King (2010) and Lapi et al. (2005) (see also Menci et al. 2008).

Assuming an isothermal gas density profile and that all the fast wind energy not associated with the ram pressure is rapidly lost to radiation, King (2010) derived the analytic solution of the equation of motion of the momentum-driven shock pattern using the shell approximation. For the region outside the black hole sphere of influence they found $R(t) \propto at + bt^{0.5} + c$ where the constants a , b , and c are determined by the black hole mass, the parameters of the galaxy potential, and by the position and the speed of the shell at time $t=0$ (see King 2010). The above relation implies $L_{kin}(t) \propto t^{-1.5}$.

Assuming a power law ambient density profile $\rho(R) \propto R^{-\alpha}$ ($2 \leq \alpha \leq 2.5$), and the Rankine-Hugoniot boundary conditions in terms of the Mach number, Lapi et al. (2005) derived self-similar solutions of the partial differential equations describing the gas flow. They found $R(t) \propto t^{2/\alpha}$ implying an outflow power $L_{kin} \propto t^{(10-5\alpha)/\alpha}$.

These models correspond to kinetic energies injected into the ISM during the outflow time-scale larger up to a factor of ~ 2 than those injected in the energy-conserving case.

3.3. Non-thermal emission produced by accelerated particles

3.3.1. γ -ray emission from neutral pion decays

CR protons can inelastically scatter off protons in the ISM to produce neutral and charged pions. Neutral pions decay into two γ -rays: $\pi^0 \rightarrow \gamma + \gamma$; while charged pions decay into secondary electrons and positrons and neutrinos: $\pi^+ \rightarrow \mu^+ + \nu_\mu$ and $\mu^+ \rightarrow e^+ + \nu_e + \bar{\nu}_\mu$; $\pi^- \rightarrow \mu^- + \bar{\nu}_\mu$ and $\mu^- \rightarrow e^- + \bar{\nu}_e + \nu_\mu$.

To calculate the hadronic component of the γ -ray spectrum and the energy spectra of secondary particles (electrons, positrons and neutrinos) we use the parametrizations derived by Kelner et al. (2006). These analytical approximations, which are based on simulations of proton-proton interactions, provide very good

Fig. 1. Residence times of CR protons (dashed) and electrons (dotted) in the CND of NGC 1068 as a function of particle's energy. Red lines $n_H=120 \text{ cm}^{-3}$, $B_{ISM}=100 \mu\text{G}$, $L_{AGN}=2.1 \times 10^{45} \text{ erg/s}$, $U_{rad}=3.7 \times 10^4 \text{ eV cm}^{-3}$, $R_{shock}=100 \text{ pc}$, and $v_{shock}=200 \text{ km/s}$; black lines: $n_H=400 \text{ cm}^{-3}$, $B_{ISM}=350 \mu\text{G}$, $L_{AGN}=4.2 \times 10^{44} \text{ erg/s}$, $U_{rad}=7.3 \times 10^3 \text{ eV cm}^{-3}$, $R_{shock}=100 \text{ pc}$, and $v_{shock}=200 \text{ km/s}$. The solid blue line indicates the time-scale of the AGN-driven molecular outflow.

accuracy over the energy range of parent protons above 100 GeV. At lower energies the spectra are calculated using the δ -functional approximation (Aharonian & Atayan 2000).

3.3.2. γ -ray emission from inverse Compton

The leptonic component of the γ -ray spectrum consists of IC scattering of the AGN radiation and non-thermal bremsstrahlung. The spectrum of photons generated per unit time due to IC scattering is (see e.g. Blumenthal & Gould 1970):

$$d\dot{N}_\gamma/dE_\gamma = \int d\epsilon n_{ph}(\epsilon) \int dE_e W(E_e, \epsilon, E_\gamma) N_e(E_e) \quad (20)$$

where

$$n_{ph}(\epsilon) = \frac{1}{4\pi c R_{out}^2 \epsilon} \frac{dL_{AGN}}{d\epsilon} \quad (21)$$

is the differential input photon number density at the location of the shock. To calculate the output spectrum we use the synthetic spectrum of a type 1 AGN as computed by Sazonov et al. (2004) normalized to the bolometric luminosity of NGC 1068. In eq. (20) N_e represents the combined primary and secondary electron/positron spectrum from pion decay, and

$$W(E_e, \epsilon, E_\gamma) = \frac{8\pi r_e^2 c}{E_e \eta} \left[2q \ln q + (1-q) \left(1 + 2q + \frac{\eta^2 q^2}{2(1+\eta q)} \right) \right], \quad (22)$$

is the scattering cross-section, taking into account Klein-Nishina effects, with $\eta = \frac{4\epsilon E_e}{m_e^2 c^4}$ and $q = \frac{E_\gamma}{\eta(E_e - E_\gamma)}$.

3.3.3. γ -ray emission from bremsstrahlung

In the case of production by bremsstrahlung the spectrum of photons generated per unit time is (Stecker 1971):

$$d\dot{N}_\gamma/dE_\gamma = c n_H \sigma_{brem} E_\gamma^{-1} \int dE_e N_e(E_e) \quad (23)$$

where $\sigma_{brem} = 3.38 \times 10^{-26} \text{ cm}^2$, and N_e represents the combined primary and secondary electron/positron spectrum.

3.3.4. Radio emission from synchrotron

The majority of the radio flux comes from non-thermal synchrotron emission. We calculate the synchrotron emission following the standard formula from Rybicki & Lightman (1979). We calculate the radio spectra due to synchrotron emission by primary electrons and secondary electrons/positrons from pion decay. The radiation spectrum of a power law electron energy distribution $N_e(E) \propto E^{-p}$ may be expressed in terms of the magnetic field B_{ISM} and the frequency ν as $F_\nu \propto B_{ISM}^{(p+1)/2} \nu^{-(p-1)/2}$. Thus the spectral shape is determined by the shape of the electron distribution: if $-p$ is the spectral index of the electron energy spectrum, the spectral index of the synchrotron emission is $-(p-1)/2$.

4. Results

Here we derive the non-thermal emission produced by CR particles accelerated in the AGN-driven outflow observed in NGC 1068 and we compare it with the γ -ray and radio spectra.

We compare the predicted γ -ray emission with the γ -ray spectrum from the 3FGL catalogue (Acero et al. 2015), and with the γ -ray spectrum obtained from our analysis of the *Fermi*-LAT data (Sect. 2.2). The *Fermi*-LAT observations do not spatially resolve the γ -ray emitting region. Therefore, we suppose that all the γ -ray flux is related to the inner $\sim 100 \text{ pc}$ of the galaxy. Conversely, the radio observations are spatially resolved. However within 100 pc the presence of the radio jet hampers the identification of any emission not originating from it or the compact nucleus. The current radio observations provides therefore only limited constraints on the cosmic ray population outside the AGN jets (see also Yoast-Hull et al. 2014; Eichmann & Becker Tjus 2016). In the following analysis we consider the magnetic field derived from the radio observations as only an upper limit to the magnetic field strength in the shock region.

We derive the γ -ray and radio emissions for AGN-driven outflows in both the energy-driven and momentum-driven scenarios (Section 3.2). We assume for the outflow radius, velocity, and kinetic power the values obtained from sub-mm interferometry: $R_{out}=100 \text{ pc}$, $v_{out}=(100-200) \text{ km/s}$, $L_{kin}=(0.5-1.5) \times 10^{42}$ (see Section 2); and for the proton and electron acceleration efficiencies the SNR values: $\eta_p=(0.1-0.2)$, and $\eta_e=(0.01-0.02)$ (Lacki et al. 2010). We vary parameters such as the spectral index (p), the AGN bolometric luminosity (L_{AGN}), the density experienced by CR particles (n_H), and the magnetic field (B_{ISM}). The spectral index is restricted to the value $p < 2.2$ since larger values are ruled out by the combination of *Fermi*-LAT and IceCube observations (Murase et al. 2013). We vary the AGN bolometric luminosity within the range $L_{AGN}=(4.2 \times 10^{44} - 2.1 \times 10^{45}) \text{ erg s}^{-1}$, and the density experienced by CR particles in the range

$n_H=(115-460) \text{ cm}^{-3}$ (see Sect. 2). In this way we are assuming that the density experienced by CR particles is equal to the average density of the CND. However, CR particles do not necessarily propagate through gas with the average ISM density. This may be because the ISM is clumpy and the accelerated particles favour high-density clumps or they propagate along path of least resistance. Thus, we also consider a simple calorimetric hadronic model in which CR protons loose almost all of their energy to hadronic collision before escaping ($F_{cal}=1$). This condition could be satisfied if $\tau_{pp} \ll \tau_{out}$ and hence if $n_H \gtrsim 10^4 \text{ cm}^{-3}$. Finally, for the magnetic field we assume values bracketed by a minimum value that is given by the volume average magnetic field strength of the CND (see Section 2) and a maximum value that is inferred from the radio observations.

The results are shown in figure 2. We find that, in the standard SNR acceleration theory, even selecting parameters to maximize the γ -ray emission, the predicted spectrum is lower than the observed data by a factor of ~ 2 at energies $E \gtrsim 1 \text{ GeV}$, and by a factor of ~ 10 at $E \approx 0.1 \text{ GeV}$.

In order to match the observed γ -ray spectrum acceleration efficiencies $\eta_p \geq 0.3$ and $\eta_e \geq 0.1$ are required. A strong coupling between the molecular medium in the CND and CR protons produced in the outflow shocks ($F_{cal} \geq 0.5$) is also necessary (see fig. 2).

In the following we study the effect of changing each of the free quantities within the above ranges.

4.1. Energy-driven and momentum-driven outflow

The degree of which the observed outflow is energy-driven or momentum-driven influences the normalization of the CR particle spectrum (eq. 16). The difference in normalization in the two outflow regimes is maximized when the residence time of CR particles is equal to the outflow time-scale. Since the residence time of CR electrons in the CND is much smaller than the outflow time-scale (see fig. 1), the leptonic components of the γ -ray spectrum and the radio spectrum are not strongly influenced by the nature on the outflow.

The residence time of CR protons is nearly equal to the outflow time-scale for ISM density $n_H = 120 \text{ cm}^{-3}$ and decreases with increasing ISM density. Thus only for low n_H values we find a significant difference in the two outflow regimes.

4.2. CR parameters: p , η_p , η_e

The slope of the hadronic component of the γ -ray spectrum reflects the slope of the underlying CR proton population p . A steeper primary CR proton spectrum correspond to a steeper γ -ray spectrum at energies $\gtrsim 1 \text{ GeV}$.

The efficiencies η_p and η_e are the normalizations of the injected primary CR protons and electrons respectively (eq. 16). Larger (lower) η_p and η_e linearly increase (decrease) the hadronic and leptonic spectral components without changing the spectral shape.

4.3. ISM density

The ISM effective density experienced by CR particles determines the efficiency of hadronic losses F_{cal} . An increase in F_{cal} augments the γ -ray emission and the number of secondaries (electrons, positrons and neutrinos) from pion decays. The ISM density also regulates the importance of bremsstrahlung and ionization losses for CR electrons.

Low density models can be distinguished observationally from the high density models by γ -ray emission below $\sim 100 \text{ MeV}$: models with low n_H are dominated by IC emission, whereas models with high n_H by bremsstrahlung emission.

4.4. Magnetic field

The magnetic field affects the spectra in several ways. It determines the critical synchrotron frequency $\nu_c \simeq (3E^2 eB)/(16m_e^3 c^5)$, at a fixed observed frequency a stronger magnetic field implies that we see lower energy electrons.

The magnetic field strength determines the importance of synchrotron cooling relative to IC, Bremsstrahlung, and ionization losses. If synchrotron cooling dominates over other cooling losses the power law index of the synchrotron radio spectrum changes from $-(p-1)/2$ to $-p/2$, and the radio luminosity approaches a maximum which is not affected by further increase in B_{ISM} . The ratio of synchrotron to IC losses is equal to $U_B/U_{rad} \propto (B_{ISM}^2 R_{out}^2)/L_{AGN}$ (eq. 8 and 3.3.2). At $R_{out}=100 \text{ pc}$ and for $L_{AGN}=(4.2 \times 10^{44} - 2.1 \times 10^{45}) \text{ erg s}^{-1}$, synchrotron losses start to dominate over IC losses ($U_B > U_{rad}$) if $B_{ISM} \gtrsim 1.3 \text{ mG}$. Finally, the magnetic field determines the maximum energy of CR protons and electrons (eq. 17-19) that in turn determines the high energy cut-off seen in the γ -ray spectrum. Sensitive TeV observations are fundamental to assess the presence of a high-energy cut-off (see fig 2). Measuring a high energy cut-off can constrain in detail acceleration mechanisms operating in the shocks since the maximum energy of accelerated particles depends by particle escape, age or size of the accelerator, and particle energy-loss processes.

Sensitive TeV observations are also fundamental to estimate the total non-thermal high energy luminosity of the source, and to constrain the power law index p of the accelerated CR proton population. To assess the performances of the present and next generation Cherenkov telescopes we show in figure 2 the differential energy flux sensitivities of the MAGIC telescopes, of the High Energy Stereoscopic System (H.E.S.S.), and of the Cherenkov Telescope Array (CTA) corresponding to 5σ level of confidence per energy bin (5 bins per decade) after 50 hours of effective observation time.

5. Discussion

5.1. Origin of the γ -ray emission

The results presented in the previous section indicate that the molecular outflow observed in the CND of NGC 1068 provide a contribution to the γ -ray emission at least comparable to that provided by SNR-driven shocks due to the starburst activity (see Yoast-Hull et al. 2014; Eichmann & Becker Tjus 2016), when the same standard particle acceleration efficiencies are assumed ($\eta_p \approx 0.1 - 0.2$ for protons, and $\eta_p \approx 0.01 - 0.02$ for electrons). We have shown that the AGN outflow model can account for the observed γ -ray emission only when larger acceleration efficiencies are assumed for protons ($\eta_p \geq 0.3$) and for electrons ($\eta_e \geq 0.1$), and for calorimetric fractions $F_{cal} \geq 0.5$.

At present, there are no clear observational support for such large acceleration efficiencies. In fact, we expect similarity between strong shocks with comparable velocity (e.g. Keshet et al. 2003). However, other parameters that determine the physics of the shock waves, like the pre-shock density and the magnetic field, in the region near the AGN could not be the same than those in the central regions of non active galaxies.

As for the calorimetric fraction, we note that if the molecular outflow is launched when the outflow of ionized gas and/or the inner jet sweeps the CND disk, they are not in the plane of the CND. However, a hint in favour of the strong coupling between CND molecular gas and the CR protons accelerated in the AGN-driven shocks comes from the chemical analysis of the molecular gas in the CND. The comparison between the abundances derived from molecular line surveys of the CND with those predicted by chemical models indicates that each sub-region of the CND could be characterized by three gas phases, two of which are pervaded by a CR ionization rate (and/or X-ray activity) enhanced by at least a factor of 10 compared to the Galactic value (Aladro et al. 2013; Viti et al. 2014, see also Spinoglio et al. 2012). In contrast, if shock acceleration is limited to a narrow zone of the CND, as suggested by preliminary ALMA observations at $\sim 0.5''$ resolution (Kohno et al. 2016), even larger CR proton acceleration efficiencies are required in order to produce the observed γ -ray emission.

Modelling the chemistry in molecular disks around AGNs is a difficult task since it is affected by the different physical components of the systems, the disk density structure, and dynamical processes (e.g. Harada et al. 2013). Larger number of molecular transitions with high resolution are therefore necessary to properly determine the chemical and physical properties of the CND.

In the case where the γ -rays are from hadronic processes, the observed γ -ray emission can provide constraints on the CR ionization rate of molecular gas in the CND. However, the CR proton parameters derived by modelling the γ -ray emission characterize the proton spectrum at energies $E_p \gtrsim 1$ GeV (threshold for pion formation), while the molecular hydrogen is mostly effectively ionized by lower energy protons. Although the latter are also likely accelerated in the shock, in order to derive the expected ionizing CR proton flux one should rely on complex extrapolations of the CR proton spectrum to energies $E_p < 1$ GeV (see e.g. Padovani et al. 2009; Schuppan et al. 2012).

An enhanced molecular ionization of the CND gas could therefore be an indication that the γ -ray emission has an hadronic component. The balance between the hadronic and leptonic contributions to the emission could constrain the origin of the γ -ray emission.

A leptonic scenario in which the γ -ray emission of NGC 1068 is produced through IC scattering of IR photons from the relativistic electrons in the misaligned jet at a few tenth of parsecs from the central source was proposed by Lenain et al. (2010). The observations of NGC 1068 with current and upcoming Cherenkov telescopes are promising to test CR acceleration models in active galaxies. Indeed, the presence of γ -ray emission in the very high energy (VHE) band could provide a hint to assess the presence of hadronic emission. The leptonic γ -ray emission hardly extends to \gtrsim TeV energies owing to the values of the shock velocity and of the magnetic field strength in the shock region (see eq. 18, and Lenain et al. 2010).

The energy range below $E \approx 100$ MeV is also crucial to constrain CR acceleration models. As shown in Section 4.3, the IC-dominated γ -ray spectrum can be distinguished from that dominated by bremsstrahlung emission at $E \lesssim 100$ MeV (see figure 2, and figure 4 of Lenain et al. 2010). At present this spectral region is not observable, the new γ -ray missions that are be-

ing planned like ASTROME⁷ and ASTROGAM⁸ may bring a breakthrough in our understanding of γ -ray spectra in active galaxies.

5.2. Neutrino fluxes

Finally, the "smoking-gun" to demonstrate the presence of a hadronic component in the γ -ray spectrum is provided by the detection of neutrino signal from NGC 1068. Indeed, in the proton-proton interactions $\sim 2/3$ of the pions produced are charged pions that decay into muons and neutrinos followed by electrons and positrons and more neutrinos (see Section 3.3.1). Neutrinos can also be created in interactions of CR protons with the ambient radiation field. Neutrinos created in proton-proton and in proton-photon interactions take $\sim 5\%$ of the initial CR proton energy. This means that 1 PeV neutrino is generated by the interaction of ~ 20 PeV CR protons. We find that the cooling time $\tau_{p\gamma}$ of 20 PeV CR protons due to the AGN radiation field in the CND of NGC 1068 is a factor (25-100) larger than the proton-proton collisional time-scale. However since $\tau_{p\gamma}$ decreases with increasing proton energy ($\tau_{p\gamma} \propto E_p^{-1}$ if the photon field is a simple power law $n(\epsilon) \propto \epsilon^{-2}$) the production of \gtrsim PeV neutrinos through photo-hadronic processes could not be negligible.

Figure 3 shows the neutrino fluxes expected from the models presented in Section 4. To calculate the neutrino energy spectra we follow the procedure described in Section 3.3.1. Neutrinos created in proton-proton interactions exhibit energy spectra that follow the initial CR proton spectrum.

In table 2 we report the total number of neutrino events expected in one year of integration time of current and upcoming neutrino detectors. This is obtained from:

$$N_\nu = T \times \int \frac{dN_\nu}{dE_\nu} A_{eff} dE_\nu \quad (24)$$

where T is the observation time, and A_{eff} is the effective area of ANTARES, IceCube, and KM3NeT as shown in fig. 3. The expected number of neutrino events collected in current neutrino telescopes during 1 year is $\lesssim 0.1$. However, our calculation suggests that in the next future, the IceCube's counterpart on the Northern hemisphere KM3NeT will be able to reveal more effectively the neutrino signal from this kind of sources. Moreover, thanks to the angular resolution of the ARCA instrument of $\sim 0.2^\circ$ for neutrino events with energy $E \gtrsim 10$ TeV (track-like events, Adrián-Martínez et al. 2016a), KM3NeT will allow to constrain effectively the position of the possible counterparts of neutrino events, thus providing a possible direct test of the AGN outflow model.

At present, the analysis of positional coincidence of neutrino events with known astrophysical objects is a difficult task owing to the poor angular resolution of current neutrino detectors. Because of these large positional uncertainties there are no yet confirmed identifications for astrophysical sources of high energy neutrino events (e.g. Aartsen et al. 2014; Adrián-Martínez et al. 2016b; The IceCube Collaboration et al. 2015).

Figure 4 shows the sky map of IceCube neutrino events as well

⁷ the sensitivity to be achieved by ASTROME⁷ for five years of survey is $\sim 10^{-12}$ - 10^{-11} erg cm⁻² s⁻¹ at $E \approx 1$ -100 MeV.

<http://astrome.in2p3.fr>

⁸ the ASTROGAM expected sensitivity for an effective exposure of 1 year is $\sim 10^{-12}$ - 10^{-11} erg cm⁻² s⁻¹ at $E \approx 1$ -100 MeV.

http://astrogam.iaps.inaf.it/scientific_instrument.html

as the location of local galaxies (i.e. with recession velocities $v \leq 1200 \text{ km s}^{-1}$) with IRAS 100 μm flux $F_{\text{IRAS}} \geq 50 \text{ Jy}$. We also highlight the galaxies detected by *Fermi*-LAT. These are non-blazar galaxies with AGN and/or starburst activity in their nuclear regions. The location of NGC 1068 is in correspondence of one of the 54 neutrino events detected by IceCube in four years of data (Aartsen et al. 2014). The fact that all the *Fermi*-LAT galaxies lie within the acceptance region of a neutrino event suggests an intriguing scenario in which one may speculate that the γ -ray emission from particle acceleration in SNR-driven and/or AGN-driven shocks could have hadronic origin.

Positional associations of the neutrino events detected by IceCube to Seyfert and starburst galaxies in the *Fermi*-LAT and IRAS catalogs have been previously reported in the literature (Emig et al. 2015; Moharana & Razzaque 2016). A statistically significant correlation was found between IceCube neutrino events and local starburst galaxies, however, the expected neutrino fluxes derived from the γ -rays detected from individual sources disfavour the scenario proposed in this paper. We expect that the situation will become clearer when KM3NeT will be operative.

	N_γ	N_{ν_μ}	N_{ν_e}
ANTARES	7×10^{-7}	-	-
IceCube	0.1	-	-
KM3NeT	-	0.6	0.1

Table 2. Predicted number of neutrino events in one year of integration time.

6. Conclusions

We compute the non-thermal emissions produced by CR particles accelerated in the shocks produced by the galactic AGN-driven outflow observed in NGC 1068. We find that, within the standard acceleration theory, the predicted γ -ray spectrum is lower than the observed data by a factor of ~ 2 at energies $E \gtrsim 1 \text{ GeV}$, and by a factor of ~ 10 at $E \approx 0.1 \text{ GeV}$. This contribution to the γ -ray emission is comparable to that provided by the starburst activity (Yoast-Hull et al. 2014; Eichmann & Becker Tjus 2016).

The analysis presented in this paper indicates that the γ -ray emission from NGC 1068 is either entirely produced by leptonic processes - as proposed in the AGN jet model by Lenain et al. (2010) - or by processes with acceleration efficiencies of protons and electrons larger than those commonly assumed in SNR-driven shocks. The latter interpretation requires either a substantial revision of the standard acceleration theory, or the condition that AGN-driven shocks are substantially different from those powered by SNR.

The AGN outflow model proposed in this paper can be directly tested by present and forthcoming instruments. The observation of NGC 1068 at TeV energies with present and next generation Cherenkov telescopes could provide stringent constraints on CR acceleration models in active galaxies by the detection of a high-energy cut-off in the γ -ray spectrum. Moreover, in the next future the CTA spatial resolution of $\sim 3 \text{ arcmin}$ at energies $E = (1-10) \text{ TeV}$ might distinguish between point-like and extended γ -ray

emission. In case of extended emission, the determination of the centroid will allow to determine if it originates from the nucleus or from the more extended starburst ring.

Another way to directly test the AGN outflow model is to look for neutrino signal. The fluxes predicted by this model indicate that the neutrino signal from NGC 1068 may be detectable by the next generation neutrino telescope KM3NeT, which, thanks to the improved angular resolution compared to the current neutrino detectors, will allow to constrain effectively the possible astrophysical sources of high energy neutrino events.

The AGN outflow model can also be indirectly tested. A potential test is to determine the CR ionization rate of the molecular medium in the CND. In fact, an enhanced molecular ionization of the CND gas could be an indication that the γ -ray emission has a hadronic component. Molecular line surveys toward the nucleus of NGC 1068 at ALMA resolution are therefore necessary to properly determine the chemical and physical properties of the CND gas.

Finally, the large efficiencies required to accelerate protons and electrons in the AGN outflow model imply a large production of CR particles. An immediate consequence is that weaker magnetic fields are required to produce the observed synchrotron emission in the radio continuum.

Table 1. NGC 1068 spectral informations derived from the *Fermi*-LAT analysis presented in this paper (Section 2.2).

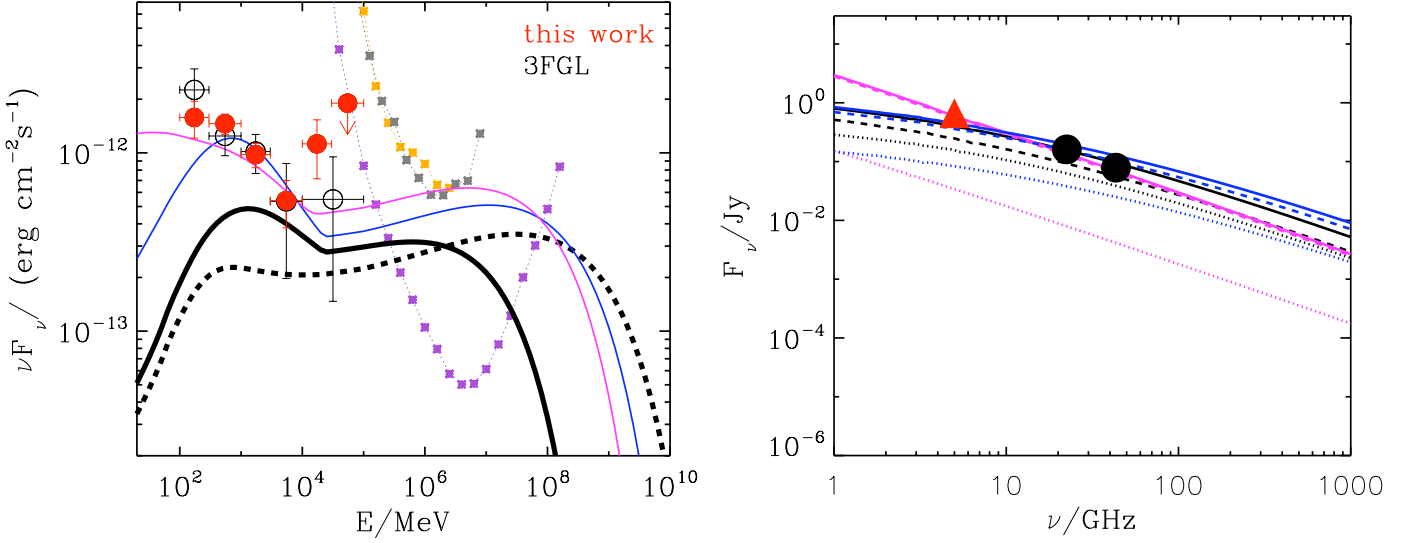

Fig. 2. γ -ray and radio spectra for NGC 1068. AGN-driven outflow parameters are set at $R_{out}=100$ pc, $v_{out}=200$ km/s, and $L_{kin}=1.5 \times 10^{42}$ erg/s; black lines: $L_{AGN}=4.2 \times 10^{44}$ erg/s, $n_H=10^4$ cm $^{-3}$, $F_{cal}=1$, $p=2$, $\eta_p=0.2$, $\eta_e=0.02$, $B_{ISM}=30$ μ G (solid) and $B_{ISM}=2$ mG (dashed); magenta line: $L_{AGN}=2.1 \times 10^{45}$ erg/s, $n_H=120$ cm $^{-3}$, $F_{cal}=0.5$, $p=2$, $\eta_p=0.5$, $\eta_e=0.4$, $B_{ISM}=250$ μ G; blue line: $L_{AGN}=4.2 \times 10^{44}$ erg/s, $n_H=10^4$ cm $^{-3}$, $F_{cal}=1$, $p=2$, $\eta_p=0.3$, $\eta_e=0.1$, $B_{ISM}=600$ μ G. γ -ray spectrum: violet dotted line: expected CTA-south differential sensitivity, from simulated data (5σ per energy bin – 5 per decade – in 50 hours, zenith angle=20 deg 6), grey dotted line: measured MAGIC differential sensitivity (5σ in 50 hours at low zenith angles <30 deg, Aleksić et al. 2016), orange dotted line: measured H.E.S.S. II differential sensitivity (5σ in 50 hours, zenith angle=18 deg, Holler et al. 2015). Data points: *Fermi*-LAT spectrum from our analysis (red filled circles), and from the 3FGL catalogue (Acero et al. 2015, black open circles). Radio spectrum: primary electrons emission (dashed line), secondary electrons/positrons emission (dotted line), total emission (solid line). Data points: total radio emission from ≈ 200 pc region (circles, Sajina et al. 2011), extra-nuclear radio emission from ≈ 1.1 kpc region (triangle, Gallimore et al. 2006). 6 <https://portal.cta-observatory.org/Pages/CTA-Performance.aspx>

Fig. 3. Left: neutrino spectra for NGC 1068. Muon neutrino flux (dotted line), electron neutrino flux (dashed line), total neutrino flux (solid line). The neutrino fluxes expected from the models in figure 2 are shown with black, blue, and magenta lines. Right: IceCube effective area (red line), ANATARES effective area (blue line), muon neutrino KM3NeT effective area (magenta dotted line), and electron neutrino KM3NeT effective area (magenta dashed line).

Fig. 4. Aitoff projection of the IceCube neutrinos in Galactic coordinate system. Red numbered points represent the location of each neutrino event and the surrounding circular areas show the respective median angular error (which includes systematic uncertainties). Black squares are local galaxies with $v \leq 1200 \text{ km s}^{-1}$ and IRAS $100 \mu\text{m}$ flux $\geq 50 \text{ Jy}$. Blue crossed squares indicate galaxies in the 3FGL catalogue (Acero et al. 2015). NGC 1068 is located at the lower left part of the map in correspondence of the neutrino ID 1.
